January 2021

EXECUTIVE SUMMARY

The Lakeland Industry and Community Association (LICA) implemented a long term Acid Deposition monitoring program in 2010 with establishment of the Moose Lake site within Moose Lake Provincial Park. A second site, the Whitney Lakes long term soil acidification monitoring site, was established in 2011, and in 2012 a third site was set up near Tucker Lake. Soil sampling and laboratory analysis of soil samples to establish baseline soil chemistry data for these sites were completed during their respective site establishment years. The intended long term monitoring interval is four years. This report presents the data from the third sampling of the Tucker Lake site carried out in the fall of 2020 and compares the data with the results of previous sampling events.

The LICA monitoring system follows the protocols of Alberta Environment and Parks (AEP) in their Long Term Soil Acidification Monitoring Program. Background information, site selection and results of the first sampling event are described in *LICA Long Term Soil Acidification Monitoring - Tucker Lake Site Establishment* (Abboud and Turchenek, 2013).

Soil acidification parameters are soil attributes that can be directly affected by acidic inputs, and which in turn could affect other components of the ecosystem. These attributes include pH, exchangeable base saturation, aluminum (Al) concentration in soil solution, base cation (BC) concentration in soil solution, and the ratio of BC to Al concentrations. Associated attributes are levels of carbon (C), nitrogen (N) and sulphur (S) in surface soil horizons. In particular, S content can increase in the LFH and surface mineral soil layers due to deposition of sulphur oxides. Carbon and N are included with S analyses because the ratios of the three elements can reveal dynamics of these nutrients over a long term.

Soil acidification parameters were examined using descriptive statistics and analysis of variance procedures to determine variability in the data and to assess if there are statistically significant differences between the means of the measured chemical parameters from the 3 sampling periods (2012, 2016 and 2020) and from the two sampling sites (North and South). Base saturation and pHc (pH of soil mixed with CaCl₂ solution) were the least variable, while in some cases BC:Al ratio and some dissolved ion concentrations had coefficients of variation exceeding 1.0 (>100%; i.e., standard deviation greater than the mean value). Total C, N and S, as well as the ratios of these with each other, were highly variable, particularly in the upper mineral layers.

Data inferences among the three sampling events are considered to pertain primarily to natural variability of the soil properties. There were small decreases in pHc and C:S ratio, and increase in total S, which suggest minor acidification had occurred in the eight year (2012-2020) period of soil chemistry monitoring. However, this was not indicated in the two other main acidification indicators, namely base saturation percentage and BC:Al aluminum ratio. The changes are considered 'minor' as pHc differs by only 0.2 to 0.3 units, which is likely not sufficient to measurably affect vegetation and soil microflora. Overall, the data suggest that slow acidification may be occurring. Assessment of these trends requires further monitoring for longer periods, which is part of the design of the LICA soil monitoring program.

1.0 INTRODUCTION

The Lakeland Industry and Community Association (LICA) implemented a long term Acid Deposition monitoring program in 2010 with establishment of the Moose Lake site within Moose Lake Provincial Park. A second site, the Whitney Lakes long term soil acidification monitoring site, was established in 2011. The Tucker Lake site was established in 2012, with soil sampling and laboratory analysis of soil samples completed to provide baseline soil chemistry data for the site. The long term monitoring program entails re-sampling of sites at four year intervals. This report presents the data from the third sampling event carried out in fall of 2020.

Background information and site selection are described in *Long Term Soil Acidification Monitoring in the LICA Study Area* (Abboud and Turchenek 2011). Establishment of the Tucker Lake site and results of the initial two sampling events are presented in *LICA Long Term Soil Acidification Monitoring - Tucker Lake Site Establishment* (Abboud and Turchenek 2013), and *LICA Long Term Soil Acidification Monitoring, Tucker Lake Site – 2016* (Abboud and Turchenek, 2017). The LICA monitoring system follows the protocols of Alberta Environment and Parks (AEP) in their Long Term Soil Acidification Monitoring Program (Roberts et al. 1989; Abboud et al. 2012). This program consists of eight monitoring sites established in the 1980s throughout the Province of Alberta. One of these sites is located within the LICA study area, thus providing a historical monitoring basis for the LICA program.

Each monitoring site consists of two sub-sites; these are referred to as the North and South sub-sites at the Tucker Lake monitoring site. The sub-sites are normally delineated by a 24 m by 24 m square area that is further subdivided into plots and subplots for replication purposes. At the Tucker Lake site, the South sub-site is 24 m by 24 m, but due to variability in topography only an 18 m by 18 m area of uniform slopes could be fitted into the North sub-site location. At each of the sub-sites (i.e., North and South), twelve replicates are taken of eight soil layers (LFH and 0-2, 2-5, 5-10, 10-15, 15-30, 30-45 and 45-60 cm layers). The report of Abboud and Turchenek (2011) should be consulted for further details of the monitoring protocol. Details of sampling methods and laboratory analysis are also provided in the report of the 2012 sampling event (Abboud and Turchenek 2013).

All soil chemical parameters were measured for all replicates and all layers in the initial monitoring events in 2010 (Moose Lake), 2011 (Whitney Lakes) and 2012 (Tucker Lake). The purpose was to establish the baseline for the entire depth of sampling. In the second and third sampling events, and in subsequent years, only the LFH, 0-2, 2-5, 5-10, and 10-15 cm depth samples will be analyzed. This is done in part to reduce the analytical costs associated with monitoring. In addition, it has been shown in the AEP long term monitoring program that any effects to date have occurred only in the surface soils layers (Abboud et al. 2012). Consequently, the long term aspect of monitoring entails determination of the acid chemistry of surface soil layers to 15 cm depth. All samples are archived and will be available for laboratory analysis in the future, should results indicate that changes are potentially occurring to depths greater than 15 cm.

2.0 METHODS

2.1 SOIL SAMPLING

Soil sampling was carried out as described in the 2011 site selection and soil monitoring report (Abboud and Turchenek (2011)).

2.2 LABORATORY ANALYSES

Soil analyses were completed at the Soil Laboratory of the Northern Forestry Centre in Edmonton, Alberta. Samples submitted to the laboratory from the field were kept frozen if they could not be immediately processed. Sample processing consisted of drying at about 30°C and then sieving to obtain the <2 mm soil fraction. Methods are as described in the 2011 soil monitoring report (Abboud and Turchenek 2011), and method references are repeated below in Table 1.

Table 1. Analytical Methods Applied in Soil Analysis

Parameter	Method	Notes
pH (CaCl ₂)	Method 3.11 in McKeague (1978)	The soil-to-solution ratio for litter (LFH) material is 1:4 and for mineral soil is 1:2. Solution is 0.1 M CaCl ₂ . Measurement is with a combination pH electrode.
Electrical Conductivity	Method 4.13 in McKeague (1978)	The EC and pH were measured in the saturated paste extract of a soil sample.
Soluble Ions	Method 3.21 in McKeague (1978)	By the saturated paste method and ICP-OES analysis of the extract for Na, K, Ca, Mg, Al, Fe, Mn and S.
Cation Exchange Capacity - Unbuffered	Method 18.2 in Carter and Gregorich (2008)	By unbuffered 0.1 M BaCl ₂ extraction, and calculation of CEC as sum of exchangeable cations.
Exchangeable Cations	Method 18.2 in Carter and Gregorich (2008)	By ICP-OES analysis for Ca, Mg, Na, K, Fe, Mn, and Al in the unbuffered BaCl ₂ extract from CEC analysis.
Total Carbon, Nitrogen, and Sulphur	Method 3.611 in McKeague (1978)	Combustion method using a LECO TruSpec CNS Carbon/Nitrogen/Sulphur Analyzer (LECO, 2006).

2.3 STATISTICS

Basic statistics (i.e., mean, standard deviation and coefficient of variability) were calculated for the acidification indicators and their input variables using MS Excel®. Coefficient of variation (CV) refers to the standard deviation divided by the mean. Analysis of variance (ANOVA) was performed on the main soil acidification variables, namely pH, base saturation, and base cation:aluminum (BC:Al) ratio, as well as some of the input variables. A two-factor ANOVA using MS Excel® was carried out to examine the differences between the two sub-sites (North and South) and the three sampling years (2012, 2016 and 2020). Tukey's Honest Significant Difference test (Steel and Torrie 1980, 1960) was subsequently applied to these attributes in order to determine whether differences in the data were statistically significant ($\alpha=0.05$ level of confidence). The statistics were based on the 12 replicates from each sub-site.

3.0 RESULTS

3.1 SOIL ACIDIFICATION PARAMETERS

Soil acidification parameters are soil attributes that can be directly affected by acidic inputs, and which in turn could affect other components of the ecosystem. These attributes include pH, exchangeable base saturation, aluminum (Al) concentration in soil solution, base cation (BC) concentration in soil solution, and the ratio of BC to Al concentrations. A discussion of these is presented in the 2011 LICA soil monitoring report (Abboud and Turchenek 2011). Of the attributes, research has demonstrated that effects on vegetation are related mainly to base saturation percentage and base cation to aluminum ratio (Ulrich et al., 1984; Sverdrup and Warfvinge, 1993). Decreases in either of these attributes can occur with addition of acidic or acidifying substances to the soil. Likewise, pH is expected to decrease. Associated attributes are levels of carbon (C), nitrogen (N) and sulphur (S) in surface soil horizons. In particular, total S content can increase in the LFH and surface mineral soil layers due to deposition of sulphur oxides. Carbon and nitrogen are included in the analyses because the ratios of the three elements can reveal dynamics of these nutrients over a long term.

3.2 SOIL MONITORING RESULTS

Soil samples from the North and South Tucker Lake sub-sites were analyzed for various soil parameters, as described above. The complete data are provided in Appendices A and B. Data in Appendix A are presented with simple statistics for each soil attribute according to soil layer and soil sub-site. Appendix B presents a listing of lab and field numbers and the analyses associated with each sample.

Tables 2, 3 and 4 summarize the data for the main acidification indicators and the parameters from which they were calculated. These tables also include basic descriptive statistics and the results of the two factor ANOVA with the Tukey's extension to the ANOVA results. The following examines some aspects of the data.

3.2.1 pHc

The data show downward trends in pHc (pH of soil mixed with CaCl₂ solution) between 2012 and 2020 in all layers and in both sub-sites of the Tucker Lake monitoring site. However, there were few statistically significant differences in soil layers among the monitoring years. There was a significant difference of 0.31 pH units in the LFH layer of the South sub-site, but a difference of 0.25 units in the North sub-site was not statistically significant. Comparing pHc in 2012 and 2020, there was a decrease in the 0-2 cm layer of 0.16 pH units in the South sub-site and 0.23 units in the North sub-site, but these differences were not significant. However, the lowest two layers (5-10 cm and 10-15 cm) showed significant differences in the North sub-site, but not the South sub-site. Variability is low, with coefficients of variation (CV) being 0.07 or lower. The significant differences in pHc among layers suggest decrease in pHc may be occurring, but the indications between sub-sites is not consistent. However, whether the differences are statistically different or not, the general trend in all layers is consistently downward.

Abbreviations: C – Total Carbon; S – Total Sulphur; N – Total Nitrogen average of 12 replicates in each sub-site

SD – standard deviation

CV – coefficient of variation

Sig - significance: a, b, ab, c, bc – significance indicators; means followed by the same letter do not differ significantly from one another at P=0.05 (Tukey's test).

3.2.2 Base Saturation

Base saturation (Table 2) is a key acidification indicator defined as the proportion of exchangeable base cations (K, Na, Ca and Mg) to the cation exchange capacity. There was a general decrease in base saturation between the first and third sampling events. Coefficients of variation range from 0.08 to 0.21 among the layers and sampling years. Significant differences occur in the 5-10 cm and 10-15 cm layers, and both increases and decreases occur among the sampling years. There were only a couple of statistically significant differences among years, but none of these were related to a decrease between the first and last monitoring events. An increase in values in the second (2016) sampling event seem to be similar to some occurrences in the provincial LTSAM program which were attributed to deposition of smoke particles from regional forest fires.

3.2.3 Cation Exchange Capacity (CEC) and Sum of Exchangeable Bases

Both CEC and sum of exchangeable base cations are variable, with CV ranging from 0.13 to 0.82 and 0.22 to 0.92, respectively (Table 2). There are no statistically significant differences in CEC or exchange bases levels among layers, except for one instance in the 5-10 cm and 10-15 cm layers of the North sub-site. These differences are not considered to be related to acidification, but rather to small differences in the composition of the soil geological parent material.

3.2.4 Base Cation to Aluminum Ratio (BC:Al) and Water Soluble Ions

The BC:Al ratios are quite variable as indicated by CV values ranging from 0.15 to 1.29 among all the soil layers and years (Table 3). Water soluble ions are likewise quite variable, with soluble Al and K having wide CV ranges up to 0.80 among all the layers, sites and years of sampling. The means of Al values among sites and years range from 0.07 to 0.33 mmol/L. The relatively high variability in these water soluble ions results in likewise highly variable ratios of base cations to aluminum.

Differences among BC:Al ratios are not significant in most layers. A significant difference in the 2-5 cm layer of the North sub-site arises from an increase (rather than a decrease) in the ratio in the 2020 samples. Relatively high ratios in 2016 samples of the 5-10 cm and 10-15 cm layers of the South sub-site also result in calculation of significant difference. With acidification, decreases of this ratio are expected; thus, the BC:Al ratios at the Tucker Lake soils show no indication of acidification.

Higher BC:Al ratios in the 0-2 cm and 2-5 cm layers, as compared to lower layers, might be a consequence of the higher base cation contents (K, Ca and Mg), which are associated with the higher organic carbon levels in the surface layers. The organic C reflects the amount of organic matter in the soil. With increasing organic matter content, there is increasing capacity to retain nutrients, including base cations. The organic matter decomposes slowly and releases nutrients, thus leading to relatively higher concentrations in the surface soil layers.

3.2.5 Total Carbon (TC)

The LFH layer is included in the analysis of TC, TN and TS because of potential for accumulation over time. Total C has relatively high variability, with CVs ranging from 0.14 to 0.84 among the sampling years and layers (Table 4). High C contents are typical of LFH layers in forest soils. Relatively higher C in the 0-2 cm and 2-5 cm mineral layers reflects the influence of the litter layer, whereby particulate or soluble C mixes or is translocated from the LFH into the upper mineral soil.

3.2.6 Total Nitrogen (TN) and Total Sulphur (TS)

As for TC, the levels of TN and TS in the mineral soil layers are highest in the 0-2 cm layer and then diminish with depth. TS is an important monitoring parameter, as sulphur can accumulate in the LFH layer and thus reflect the amount of deposition at a site. Both sub-sites show a significant increase of TS in the LFH layer in 2020 as compared to the previous two sampling events. The changes range from 0.07% to 0.011%. TN and TS contents are low in the mineral soil layers, and they display variability similar to TC (Table 4).

3.2.7 C:N, C:S and N:S Ratios

A significant decrease in the 2020 C:S and N:S ratios of the LFH horizon in both sub-sites corresponds with the increase in TS noted above. Significant N:S differences are indicated in the lower three soil layers at both sub-sites, but the ratios are increases rather than decreases in the ratio. These are difficult to explain in terms of possible deposition of TN and TS, and are more likely attributable to variability in site-specific conditions.

4.0 CONCLUSION

Soil acidification parameters were examined using descriptive statistics and analysis of variance procedures to determine variability in the data and to assess if there are statistically significant differences between the means of the measured chemical parameters from the 3 sampling periods (2012, 2016 and 2020) and from the two sampling sites (North and South). Base saturation and pHc were the least variable, while BC:Al ratio had CVs up to 1.29 (i.e., 129%). Total C, N and S were also examined, with ratios of TC and TN to TS calculated to observe possible trends in S accumulation over the long term. Levels of each of these were quite variable, particularly in the upper mineral layers.

TC, TN and TS contents are highest in the LFH layer and in upper mineral soil layers (0-2 cm and 2-5 cm). The TC reflects the amount of organic matter in the soil. Differences in other parameters such as cation exchange capacity, base cations, BC:Al ratio, TN and TS follow the TC differences because of the adsorptive capacity of organic matter for cations, and because TS and TN are generally in organic form in the soil.

The above observations of decreases in pHc, TS and C:S ratio suggest that minor acidification has occurred in the eight year (2012-2020) period of soil chemistry monitoring. However, this was not indicated in the two other main acidification indicators of base saturation percentage and base cation to aluminum ratio. The changes are considered small as pHc (in particular) differs by only 0.2 to 0.3 units, which is likely not sufficient to measurably affect vegetation and soil microflora. Overall, the data suggest that slow acidification may be occurring. Assessment of these trends requires further monitoring for longer periods, which is part of the design of the LICA soil monitoring program.

* LFH layers were analyzed only for pHc.

cmol/kg – centimoles per kilogram soil; pHc – pH of soil sample suspended in 0.1 M CaCl₂

* Sat'n – percentage by weight of water in saturated paste used to measure E.C. and to extract ions; E.C. – electrical conductivity; pH (Ext.) – pH of the extract from a saturated paste sample of soil; mg/L – milligrams per litre; BC:Al – ratio of the sum of K, Ca and Mg to Al, after conversion of units in mg/L to millimoles/L
